Abstract—A hardware detector for constant envelope quadrature-quadrature phase-shift keying (CEQ²PSK) is proposed. It uses appropriate hard decisions; yet, it achieves optimum probability of bit error performance, unlike the suboptimum detector of Saha and Birdsall. This optimum performance is verified through Monte Carlo computer simulations. Additionally, a more correct expression is given for the probability of bit error performance for CEQ²PSK, which gives the gain over non-constant Q²PSK as 1.44 dB, rather than the previously published value of 1.76 dB.

Index Terms—Quadrature-quadrature phase shift keying, constant envelope, optimum detector, four-dimensional modulation.

I. INTRODUCTION

Quadrature-quadrature phase-shift keying (Q²PSK) and constant envelope Q²PSK (CEQ²PSK) were introduced by Saha and Birdsall in [1]. A simple block encoder of rate 3/4 at the input of a Q²PSK modulator is used to produce a set of 8 biorthogonal codewords given by the constant envelope signals. Constant amplitude is desirable in nonlinear channels; it avoids the variations in phase produced by changing amplitude, which in turn has detrimental effects in the bit error rate for coherent demodulation. The constant envelope feature in CEQ²PSK is achieved at the expense of bandwidth efficiency because the information transmission rate is 3/(2T) for CEQ²PSK while it is 2/T for non-constant Q²PSK.

It is shown in [1] that CEQ²PSK can provide a 50 percent increase in bandwidth efficiency over minimum shift keying (MSK) at the cost of 0.7 dB increase in the average bit energy, assuming bandlimiting has taken place at the transmitter and receiver, through the use of sixth-order Butterworth filters with half power bandwidth equal to 1.2/T, where the bit rate is 2/T. The information bit transmission rate is 3/(2T). To achieve this performance an optimum receiver is needed; to date, however, no simple optimum hardware receiver has been proposed for this modulation scheme. Indeed, Saha and Birdsall recognized that a nonoptimum receiver based on hard decisions might be of interest for its simplicity. The simple hardware receiver provided by Saha and Birdsall performed substantially worse than the optimum, as seen in Fig. 11 of [1].

The greater flexibility for spreading afforded by higher dimensional modulation schemes such as Q²PSK and CEQ²PSK was exploited in [2] for direct-sequence spread spectrum systems (DSSS).

A hybrid block-convolutional coding scheme for CEQ²PSK is shown in [3] to improve performance by 1.5 dB at bit error rate (BER) of 10⁻⁴ both in additive white Gaussian noise (AWGN) and Rician fading channels with moderate fading. More substantial improvements are obtained with more severe fading. Saha and Birdsall’s sub-optimum decoder is used there also.

Digital implementations of CEQ²PSK transmitter and receiver are discussed in [4], while carrier phase and clock recovery in CEQ²PSK using a data-aided algorithm are investigated in [5]. The receiver in [4] is an implementation of Saha and Birdsall’s non-optimum receiver and the practical curve in Fig. 4 of [4] is close to the non-optimum detection curve in Fig. 11 of Saha and Birdsall’s original paper [1]. That receiver, then, does not optimally detect CEQ²PSK, whereas ours does. Our method requires five hard-limiters and the decision vector is just the correct combination of four of these hard-limited outputs.

An optimum receiver for minimum bandwidth Q²PSK was proposed in [6]; it employs a matched filter receiver with hard-limiter detectors that uses two hard-limiters to form a decision variable for one of the outputs. The method in [6] still requires a maximum likelihood (ML) Viterbi decoder to form the decisions for the other three quantities to be decoded.

We will show in this paper that, fortunately, a much simpler optimum receiver for CEQ²PSK can be implemented in hardware using hard decisions.

A final contribution of this paper is to give a more accurate gain of CEQ²PSK over Q²PSK. Saha and Birdsall claim in [1] that CEQ²PSK provides 1.76 dB of gain over non-constant envelope Q²PSK. However, it is shown here that this figure is too optimistic, because it ignores the effects of the error coefficient, which will reduce this gain by about 0.32 dB to around 1.44 dB.
The received CEQ²PSK signal is assumed to have been corrupted by additive white Gaussian noise (AWGN) with two-sided power spectral density $N_0/2$ in each of the four dimensions. It is also assumed that there is no bandlimitation in the channel, other than that provided by the integrate-and-dump filters that are part of the demodulator. Hence, the received demodulated signals, which are sampled every $2T$ seconds, can be represented as:

$$s(t) = [a_1(t), a_2(t), a_3(t), a_4(t)].$$  \hspace{1cm} (2)

Furthermore, (1) can be written as

$$s(t) = A(t) \cos(2\pi f_c t + \theta(t)),$$  \hspace{1cm} (3)

where $\theta(t)$ is the carrier phase and $A(t)$ is the carrier amplitude given by

$$A(t) = \left[2 + (a_1a_2 + a_3a_4)\sin \frac{\pi t}{T}\right]^{1/2}.$$  \hspace{1cm} (4)

Clearly, for the envelope to be a constant and produce CEQ²PSK we must have $a_1a_2 + a_3a_4 = 0$. Therefore, the eight possible transmitted four-dimensional (4D) signals for CEQ²PSK are $S_1=[a, a, b, -b]$ or $S_2=[a, -a, b, b]$, where $a, b$ are either +1 or -1.

The received CEQ²PSK signal is assumed to be two-dimensional (2D) signals for CEQ²PSK are $S_1=[a, a, b, -b]$ or $S_2=[a, -a, b, b]$, where $a, b$ are either +1 or -1.

The remainder of this paper is organized as follows: In Section II we briefly review CEQ²PSK. Our new optimum hardware detector for CEQ²PSK is detailed in Section III. The performance of the detector is evaluated in Section IV. Concluding remarks and references follow.

II. BRIEF REVIEW OF CEQ²PSK

A non-constant envelope Q²PSK signal can be written as

$$s(t) = a_1(t) \cos \left(\frac{\pi t}{2T}\right) \cos(2\pi f_c t) +$$

$$+ a_2(t) \sin \left(\frac{\pi t}{2T}\right) \cos(2\pi f_c t) +$$

$$+ a_3(t) \cos \left(\frac{\pi t}{2T}\right) \sin(2\pi f_c t) +$$

$$+ a_4(t) \sin \left(\frac{\pi t}{2T}\right) \sin(2\pi f_c t),$$  \hspace{1cm} (1)

where $f_c = n/4T$ is the carrier frequency, with $n$ any integer greater than or equal to two, $\{a_i(t), i = 1, 2, 3, 4\}$ are four data streams that have been demultiplexed from a binary data source of bit rate $2T$. Each data pulse in the demultiplexed streams is a rectangular shaped pulse with strengths $\pm 1$. With the given restriction on carrier frequency, (1) can be written as a vector as

$$s(t) = [a_1(t), a_2(t), a_3(t), a_4(t)].$$  \hspace{1cm} (2)

Furthermore, (1) can be written as

$$s(t) = A(t) \cos(2\pi f_c t + \theta(t)),$$  \hspace{1cm} (3)

where $\theta(t)$ is the carrier phase and $A(t)$ is the carrier amplitude given by

$$A(t) = \left[2 + (a_1a_2 + a_3a_4)\sin \frac{\pi t}{T}\right]^{1/2}.$$  \hspace{1cm} (4)

The key to developing an optimum hardware-based detector is to discover functions of the received demodulated signals that can be hardlimited, without compromising this critical ratio. The method to do this is described in what follows. The result of the development is shown in Fig. I, where our complete CEQ²PSK receiver, including demodulator and detector, is shown.

First, assume that a member of $S_1$ was transmitted. Then, as is shown below, it is easy to detect which member of $S_1$ was transmitted, by hardlimiting. This produces the estimate $\hat{S}_1 = [\hat{a}, \hat{a}, \hat{b}, -\hat{b}]$, one of four possible symbols.

Second, assume that a member of $S_2$ was transmitted. Again, hardlimiting is used to determine which member of $S_2$ was transmitted, and produce the estimate $\hat{S}_2 = [\hat{a}, -\hat{a}, \hat{b}, \hat{b}]$, one of four possible symbols.

Now, thirdly, we must decide whether a member of $S_1$ or $S_2$ was transmitted. Let $d = 1$ if the transmitted signal belongs to $S_1$, and $d = 0$ if it belongs to $S_2$. It is also straightforward to determine $\hat{d}$, the estimate for $d$, by hardlimiting. Indeed, this is the function of the $F(\cdot)$ block of Fig. 1 which requires four absolute value circuits and one hardlimiter, as we will prove shortly.

Fourthly, based upon the decision of the previous step, the detector must send the correct of the two detected symbols to the output. This task is performed by the four-pole double-throw electronic switch in Fig.1. Mathematically, the detected CEQ²PSK symbol can be described by

$$\hat{S} = \hat{d}\hat{S}_1 + (1 - \hat{d})\hat{S}_2.$$  \hspace{1cm} (6)

where $m$ is an integer, $n_i(2mT), i = 1, 2, 3, 4,$ is a zero-mean normal random variable with variance $\sigma^2 = N_0/2T_c$, with $T_c$ the signal length, which is equal to $2T$.
As mentioned earlier, it is necessary to detect which member of $S_1$ has been transmitted. To do this, we let $w = a_{1r} + a_{2r}$; for all members of $S_1$ this yields $w = 2a + n_1 + n_2$. Notice that $w$ can be considered a bipolar binary signal which can be detected by symmetric hard-limiting. Furthermore, for this binary signal, $\sigma^2_{\text{free}} = 16$ and the variance of $n_1 + n_2$ is $2\sigma^2$. Hence, the critical ratio remains unchanged at $8/\sigma^2$. Similarly, we let $y = a_{3r} - a_{4r}$. Then, $y = 2b + n_3 - n_4$. Again, $y$ can be considered a bipolar binary signal easily detected by hard-limiting, with no change in the critical ratio. Therefore, the detected 4D codeword for $S_1$ can be written as $\hat{1} = \text{sgn} w, \text{sgn} w, \text{sgn} y, -\text{sgn} y$, where $\text{sgn}(v) = 1$ for $v \geq 0$, and $\text{sgn}(v) = -1$ for $v < 0$.

In like fashion, it is easy to detect which member of $S_2$ was transmitted. Indeed, $\hat{S}_2 = [\text{sgn} x, -\text{sgn} x, \text{sgn} z, \text{sgn} z]$, where $x = a_{1r} - a_{2r}$ and $z = a_{3r} + a_{4r}$.

Also, as mentioned earlier, there is a need to determine $\hat{d}$. The method to do this will now be described. Notice that if a member of $S_1$ is transmitted and noise is ignored, the four possible values for $u = [w, x, y, z]$ are $[200200], [2020200], [-202020]$, and $[-20020]$, and therefore we have $|u| = \|w|, |x|, |y|, |z|\| = [200200].$ On the other hand, if a member of $S_2$ is transmitted, $|u| = [02020]$. 

Lucky, the binary vector $|u|$ does not compromise the critical ratio. Hence, if $\left\{ \|w| - 2\right\|^2 + \|x\|^2 + \|y| - 2\right\|^2 + \|z\|^2$ <

\[ |w|^2 + \left(\|x\| - 2\right)^2 + \|y\|^2 + \left(\|z\| - 2\right)^2 \]

then $\hat{d} = 1$, and it is determined that $S_1$ was transmitted. However, if the inequality is not satisfied, $\hat{d} = 0$, and it is determined that $S_2$ was transmitted. Furthermore, the above inequality simplifies to $|w| + |y| > |x| + |z|$. Hence,

$$\hat{d} = \frac{1}{2} \left\{ \text{sgn}|w| + |y| - |x| - |z| \right\} + 1.$$ (7)

The function block $F(\cdot)$ in Fig. 1 computes the result of (7) and therefore determines $\hat{d}$, the estimate of the unipolar binary variable $d$, which in turn activates the switch to pass the correct symbol (from $\hat{S}_1$ if $\hat{d} = 1$, from $\hat{S}_2$ if $\hat{d} = 0$) to the output.

Superficially, Fig. 3 of [4] resembles our receiver. The summers there, however, are performing a different function than our summers: theirs are simply forming the decision variables with two of them just clipping, which means that they are not detected optimally, as the squared distance is only 4 whereas the squared distance between nearest CEQ2PSK symbols is actually 8. On the other hand, our summers are ensuring that the critical ratio is maintained.

Also, the decoders in [1, 3, 4] assume that correct decisions about $a_1$ and $a_3$ have been made and use these along with the estimates $a_2$ and $a_4$ to make decisions about $a_2$.

**IV. PERFORMANCE VERIFICATION OF OUR DETECTOR**

In order to verify the derivations in the previous section, Monte Carlo simulations were performed. For each signal-to-noise ratio (SNR), i.e., $E_b/N_0$, the simulation ran until twenty symbol errors were committed. According to [7], this allows
the probability of bit error to be estimated with a standard deviation equal to less than half of the true probability of bit error value.

The theoretical probability of symbol error is given by

\[ P_s(E) = K \text{erfc} \left( \frac{3E_b}{2N_o} \right), \]  

(8)

where \( \text{erfc}(\cdot) \) is the complementary error function, and \( K \) is the error coefficient normalized to 2D, equal to \( N/2 \), where \( N \) is the average number of neighbors from a given symbol at a squared distance of eight. For CEQ^2PSK, it is easily verified that \( N = 6 \) and therefore \( K = 3 \).

To find the probability of bit error, \( P_b(E) \), it is necessary to know how the three information bits are mapped to the eight 4D symbols. Ideally, a Gray code would be used to do this, so that one symbol error causes only one bit error. However, it is not possible to do this (because there are six neighbors and the Gray code only allows three). The best that can be achieved is an average of 1.5 bit errors for each symbol error.

For our simulations, the three information bits were assigned to \( a_1, a_2, \) and \( a_3, a_4 \). was then derived to satisfy the constant amplitude condition \( a_1a_2 + a_3a_4 = 0 \). With this mapping, there are an average of one and a half bit errors for every symbol (3 information bits) error. Hence,

\[ P_b(E) = P_s(E)/2 = 1.5 \text{erfc} \left( \frac{3E_b}{2N_o} \right). \]  

(9)

This means that the error coefficient is 1.5 and not 0.5 as Saha and Birdsall assumed in [1]. Hence, the SNR suffers a loss of about 0.2 \( \log(3)/\log(2) \) or 0.32 dB as given by Forney [8]. The gain, then, of CEQ^2PSK over non-bandlimited non-
constant Q^2PSK is not 1.76 dB, but more like 1.44 dB. This was corroborated during our simulations also.

The experimental probability of bit error is plotted in Fig. 2 (shown as asterisks), along with the theoretical CEQ^2PSK curve from (9) and the curve for non-constant Q^2PSK. As can be seen, there is very good agreement between the theoretical value and the Monte Carlo simulation experimental results. We also see in Fig. 2 that at BER of \( 10^{-6} \) the gain of CEQ^2PSK over Q^2PSK is about 1.4 dB.

Additionally, the optimum detector was simulated simultaneously with our new detector. No bit errors were discovered for our proposed detector that were not also found for the optimum detector. Thus, the proposed hardware detector does indeed give optimum performance, as claimed.

V. CONCLUSIONS

We have presented an optimum hardware detector for constant envelope quadrature-quadrature phase shift keying (CEQ^2PSK). Five hardlimiters, four adders, four absolute value circuits, two inverters, and a four-pole double-throw switch are needed to implement the decoder. Monte Carlo simulations show that the performance indeed matches the theoretical value for bit error probabilities. The gain of CEQ^2PSK over non-constant Q^2PSK was shown to be around 1.44 dB.
